I. INTRODUCTION

Two-dimensional, Eulerian, hydrodynamic, computer codes have been used for many years to solve hypervelocity impact problems. To deal with the problem of a normal impact of a rod on a plate, these codes employ cylindrically symmetric coordinates (r,z). Since more and more impact problems of interest are asymmetric in nature (such as oblique impacts) and computers have become faster and larger in memory, three-dimensional, Eulerian, hydrodynamic, computer codes have been pressed into service over the past few years. 1, 2, 3, 4, 5 Compared to two-dimensional codes, these three-dimensional codes require more computational cells and, therefore, longer running times.

As a means of reducing the running time for a three-dimensional impact problem or because a three-dimensional hydrodynamic code might not be available, a two-dimensional (x,y) simulation of the problem is employed. In this study, the validity of these computations is examined.

The problem to be studied is the penetration of a 25.5-mm steel plate by a copper, shaped-charge jet, which is simulated by a 6-mm, semi-infinite, copper rod impacting normally on the plate at 7.5 km/s. Penetration, hole growth and shape, shock-wave propagation, and spallation are some of the impact phenomena that are examined.

In order to determine some characteristics of the two-dimensional code, which is used in this study, a problem of a semi-infinite, copper mass impacting on an infinite steel plate (a one-dimensional problem) was run on the computer.

The one-dimensional case was followed by several two-dimensional cases. The first of these used cylindrically symmetric (r,z) coordinates

to provide what we shall call the true finite-difference solution to the impact problem under consideration. The cylindrical geometry for this case is shown in Figure 1.

Three other two-dimensional cases were run; however, in these cases, a Cartesian (x,y) coordinate system was used. In these cases the impact problem was simulated by a semi-infinite copper plate impacting the target plate. See Figure 1 for a pictorial view of the slab geometry. In these cases, there is no material flow normal to the x,y plane. In each case a different copper plate thickness was used, and the results of the computations were compared to the true finite-difference solution.

Figure 1 also shows the rectangular geometry for the final case, that being a semi-infinite, square, copper bar impacting on an infinite steel plate. The results of this run were also compared to the true finite-difference solution.

II. COMPUTER CODES

The DORF-9 code⁶ was used to generate data for the one and two-dimensional treatments of the problem. DORF-9 is a two-dimensional, multimaterial, continuous, Eulerian, hydrodynamic code. An option of Cartesian (x,y) coordinates or cylindrically symmetric (r,z) coordinates is provided. Also, tracer particles, which play a passive role in the computations, can be used to provide a Lagrangian look to the plotted output of penetrator-target deformation. Tillotson's form of the equation of state was used.⁷

A three-dimensional solution to the problem was obtained by the TRIDORF code 8 with Tillotson's equation of state. It also is a multimaterial, continuous, Eulerian, hydrodynamic code with an option for using tracer particles. This code uses Cartesian (x,y,z) coordinates. Both codes were run on BRLESC-2, a digital computer located at the Ballistic Research Laboratory.

III. ONE-DIMENSIONAL THEORY

The shock wave diagram shown in Figure 2 was constructed by using one-dimensional shock-wave theory coupled with Tillotson's equations of

state 7 for copper and iron. Initially the interface of the copper projectile and the steel target plate is located at 15.0 mm with the target extending from 15.0 to 40.5 mm. The motion of the semi-infinite projectile is in the positive direction at 7.5 km/s. Upon impact (t=0), a transmitted shock wave, U, propagates into the target at 9.76 km/s until it reaches the back of the target where it is reflected into the target as a centered rarefaction wave, with a leading edge, R, traveling at a speed of 5.07 km/s. When the leading edge passes through the interface, I, the sound speed of the copper changes the speed of the wave, now designated as S, to 4.88 km/s.

Also, at the instant of impact, a shock wave, V, is reflected into the projectile at 1.93 km/s without any disturbance to the wave over the time period of the diagram. The material between U and V moves with a particle velocity of 3.92 km/s. This is also the speed of the interface, I, until its encounter with R. The interface motion was not calculated past this point. The shock pressure of the material between U and V is 3.01 Mbar. The back of the target is accelerated by the reflection of U to 7.84 km/s (twice the particle velocity).

IV. ONE-DIMENSIONAL PROBLEM

The two-dimensional DORF-9 code was used in a one-dimensional mode in order to establish some characteristics of the code. Uniform computational cell widths of 0.5 mm were setup over a distance of 50 mm. The steel target extended from 15.0 to 40.5 mm; the copper penetrator extended from 0.0 to 15.0 mm. To simulate a semi-infinite penetrator, boundary conditions were specified to feed penetrator material, in the positive direction, into the computational cells. The boundary at the 50-mm position was transmittive, permitting material to flow out of the computational region.

The cells, occupying the initial position of the penetrator, were given the following initial conditions:

- 1. Density = 8.9 Mg/m^3 .
- 2. Pressure = 0.0 Mbar.
- 3. Velocity = 7.5 km/s.
- 4. Specific internal energy = 0.0 J/g.

The same initial conditions were given to the cells occupying the initial position of the target except that the density was 7.86 $\rm Mg/m^3$ and the velocity was zero.

Tracer particles were positioned at 0.5-mm increments along the penetrator and target; furthermore, tracer particles were fed into the computational cells with the penetrator material being supplied into the computational grid.

The motion of the tracer particles is shown in Figure 3. A change in the direction of the tracer particle path indicates the location of a shock wave or rarefaction. By transferring the shock diagram in Figure 2 to Figure 3, a good agreement between the exact solution and the finite-difference solution to the problem is indicated.

Pressure profiles are shown in Figure 4 for the first 17 computational cycles. Since the pressures are plotted at the centers of each cell, the initial rise of the pressure can be observed at y = 15.25 mm. In 7 cycles (0.16 μs) the pressure peaks after overshooting the theoretical shock pressure of 3.01 Mbar; then, the transmitted and reflected shock fronts can be seen to move away from the initial point of impact (y = 15.0 mm) as indicated previously in Figure 3. By cycle 17 (0.30 μs) the pressure plateau is established in the neighborhood of 3 Mbar. Note that instead of the theoretical pressure step wave, each of the shock-wave fronts is smeared over 4 or 5 cells. This is typical of Eulerian hydrodynamic codes.

Figure 5 shows the pressure profile at 1.5 μs . The pressure plateau is at 3.01 Mbar with overshoots at each end of the plateau. The particle velocity in the region of the pressure plateau is 3.92 km/s, agreeing with the theoretical value. The triangular symbol at 21 mm indicates the position of the penetrator-target interface. The general shape of the pressure and velocity profiles remains the same until the forward moving shock wave reaches the back of the target (y = 40.5 mm) at about 2.6 μs . The rarefaction wave, moving back into the target, is shown at 4.0 μs in Figure 6. Note that the material near the back of the target was accelerated by the reflection of the shock wave.

Figures 2 - 6 show some of the characteristics of an Eulerian code. The agreement of the one-dimensional computations with theory gives us confidence in the code when it is applied to this class of impact problems.

V. TWO-DIMENSIONAL PROBLEM WITH CYLINDRICAL GEOMETRY

The DORF-9 code was used to solve the following problem: The penetration of an infinite steel plate, 25.5-mm thick, impacted upon by a 6-mm, semi-infinite, copper rod at 7.5 km/s. A computational grid was laid out to cover the cross-sectional region of interest of the rod-target configuration with the rod's centerline coinciding with the z-axis. See Figure 7. The overall dimensions of the grid was 25 mm by 50 mm with a corresponding grid size of 50 by 100 cells. A uniform grid was used with each toroidal computational cell having a 0.5-mm cross section.

The target was initially bounded by the planes z=15.0 mm and z=40.5 mm, the former being the front surface of the target. The rod was initially bounded by the z=0 and 15.0 mm planes and the cylinder, r=3 mm. Since the rod's initial motion was in the positive z-direction,

the bottom boundary of the grid was specified to feed rod material into grid as a simulation of a semi-infinite rod. The right boundary of the grid was selected to be transmittive thus allowing the simulation of an infinite plate. The top boundary was also transmittive, permitting material to flow out of the region of interest.

The cells, occupying the initial volume of the rod, were given the following initial conditions:

- 1. Density = 8.9 Mg/m^3 .
- 2. Pressure = 0.0 Mbar.
- 3. Radial velocity = 0.0 km/s.
- 4. Axial velocity = 7.5 km/s.
- 5. Specific internal energy = 0.0 J/g.

Similar initial conditions were given to the cells occupying the initial volume of the target except that the density was that of the steel target material, $7.86~Mg/m^3$, and the axial velocity was zero.

Tracer particles were positioned at 0.5-mm increments in the rod and target along the axis of symmetry. Also, tracer particles were fed into the grid with the rod material being supplied into the computational grid. Figure 8 shows the motion of these tracer particles along the axis of symmetry. A change in the direction of the tracer particle paths indicates the location of a shock wave. A transmitted wave and reflected wave emanate from the point of impact (z = 15.0 mm). Initially both of these waves have the speeds determined in the one-dimensional case. See Figure 3. However, after about 0.34 µs, the rarefection wave from the cylindrical free suface of the rod reaches the axis of the rod and relieves the pressure in the shock wave moving into the rod. The reflected shock wave never traveled more than 2 mm from the point of impact before turning and traveling in the same direction as the rod. Note that the tracer particle on the back surface of the target moves at a lower speed after encountering the transmitted shock wave than one-dimensional theory suggests.

The pressure of the transmitted shock wave is relieved by the front surface of the target, thereby causing the wave to move at a lower speed than predicted by one-dimensional theory.

Pressure profiles along the axis of symmetry are shown in Figure 9 for the first 23 computational cycles (0.4 μs). Since the pressures are plotted at the centers of each cell, the initial rise in pressure is located around z = 15.25 mm. In 8 cycles (0.09 μs) the pressure peaks after overshooting the theoretical shock pressure of 3.01-Mbar. Thereafter, the transmitted and reflected shock fronts form and move away from each other. Unlike the constant pressure profile of the one-dimensional case, the pressure plateau in Figure 9 decays.

Pressure and particle velocity profiles along the axis of the rod-

target configuration are shown in Figures 10 - 13. The triangular symbol denotes the location of the interface on the axis of symmetry. The peak pressure of about 0.7 Mbar, shown at 2.0 μs , persists until it is affected by the pressure release wave coming off the back surface of the target (z = 40.5 mm) at about 4.2 μs .

Figure 14 shows radial pressure profiles at 0.5 μs intervals in the 15.25-mm z-plane, which is 0.25 mm from the front surface of the target. The radial pressure in the rod, having a radius of 3 mm, can be observed to be decreasing with time. Also, the radial propagation and decay of the shock wave in the target are illustrated.

In addition to the tracer particles which were positioned along the axis of symmetry, tracer particles were positioned along the free surfaces of the target and the rod. When the coordinates of these tracer particles are line-plotted, the deformation of the rod and target can be pictured as in Figures 15 - 18. Note that the back surface of the target starts to bulge between 4 and 5 μs . Tracer particles were also positioned within the rod and the target as shown in Figure 15. The tracer particles in the copper rod are depicted by triangular symbols; square symbols depict particles in the steel target. As time progresses, these tracer particles show the flow patterns in the rod and the target.

VI. TWO-DIMENSIONAL PROBLEMS WITH SLAB GEOMETRY

The DORF-9 code, in a two-dimensional x,y-mode, was used to solve the following: The penetration of an infinite steel plate, 25.5-mm thick, impacted upon by a semi-infinite, copper plate at 7.5 km/s. Three thicknesses of the penetrator were considered: 6 mm, 4 mm, and 3 mm. The computational grid was laid out to cover the cross-sectional region of interest of the penetrator-target configuration with the plane of symmetry passing through the y-axis. See Figure 19. The overall grid was 25 mm by 50 mm with the corresponding grid size of 50 by 100 cells. A uniform grid was used with each computational cell having a 0.5-mm square cross section and a unit length.

The boundary conditions for the grid and the location of the target were the same as in the cylindrical geometry case. The semi-thicknesses of the penetrators, 3 mm, 2 mm, and 1.5 mm, were represented by 6, 4, and 3 cells, respectively.

The cells, occupying the initial volume of the penetrator, were given the following initial conditions:

- 1. Density = 8.9 Mg/m^3 .
- 2. Pressure = 0.0 Mbar.
- 3. X-component of velocity = 0.0 km/s.
- 4. Y-component of velocity = 7.5 km/s.
- 5. Specific internal energy = 0.0 J/g.

Similar initial conditions were given to the cells occupying the initial volume of the target except that the density was that of the steel target material, $7.86~Mg/m^3$, and the y-component of the velocity was zero.

Tracer particles were positioned at 0.5-mm increments in the penetrator and target along the y-axis. Also, tracer particles were fed into the grid with the penetrator material being supplied into the computational grid. Figures 20 - 22 show the motion of these tracer particles along the y-axis. A transmitted shock wave and reflected shock wave, located by the change in the direction of the tracer particle paths, emanate from the point of impact (y = 15.0 mm). Initially both of these waves have the speeds determined in the one-dimensional case. However, after about 0.34, 0.23, or 0.17 μs for penetrator thicknesses of 6, 4, and 3 mm, respectively, the rarefaction wave from the sides of the penetrator plate reaches the center plane of the penetrator.

The effects of decreasing the penetrator thickness are to decrease the speed of the transmitted shock wave and to decrease the distance that the reflected shock wave travels from the point of impact before turning and traveling in the same direction as the penetrator. This distance never exceeded 2 mm. The speed attained by the back of the target decreases as the penetrator thickness decreases.

Pressure profiles along the y-axis are shown in Figures 23 - 25 for the first 23 computational cycles (0.4 μs). Since the pressures are plotted at the centers of each cell, the initial rise in pressure occurs around y = 15.25 mm. For all three cases, in 8 cycles (0.09 μs) the pressure peaks after overshooting the theoretical shock pressure of 3.01 Mbar. Comparing the 23rd cycle for each case, we see that the magnitude of the pressure profiles decreases as the penetrator thickness is decreased.

Pressure and particle velocity profiles along the y-axis, for the three cases, are shown in Figures 26 - 37. The triangular symbol denotes the location of the interface on the y-axis. The decrease in the pressure with a decrease in penetrator thickness is illustrated in these figures.

A comparison of pressure profiles at 0.5- μ s intervals in the 15.25-mm y-plane are shown in Figure 38 for the three slab geometries. This y-plane is in the target, 0.25 mm from the front surface. Lower pressures are associated with thinner penetrators.

The positions of the tracer particles, which were initially positioned on the front and back surfaces of the target and the free side of the penetrator, were line-plotted to illustrate the deformation of the penetrator-target configuration. See Figures 39 - 50.* Several penetrator thickness effects are shown. The hole size is decreased

*Note: If the distance between two tracer particles becomes too great, the line plots do not give a true picture of the penetrator-target interface. See Figure 47 (3-mm penetrator).

and the bulge size on the back of the target decreases as the thickness is decreased. The triangular symbols in these figures depict the flow patterns for the copper penetrator; the square symbols, the steel target.

VII. PROBLEM WITH RECTANGULAR GEOMETRY

The TRIDORF code was used to solve the following problem: The penetration of an infinite steel plate, 25.5-mm thick, impacted upon by a semi-infinite, copper bar at 7.5 km/s. The cross section of the bar is a 5.317-mm square, approximately the same cross-sectional area as that of a 6-mm rod. The computational grid was laid out as shown in Figure 51. The overall size of the grid was 25 mm by 50 mm by 25 mm with a corresponding grid size of 15 by 49 by 15 computational cells in the x, y, and z directions, respectively. A non-uniform grid was used, resulting in a rectangular prism as a computational cell. Table I gives the grid coordinates and cell dimensions, dx, dy, and dz. The cell indices are I, J, and K in the x, y, and z directions, respectively.

From the geometry of the problem, the x-coordinate and z-coordinate planes were selected as planes of symmetry with the y-axis being the line of symmetry. Initially, one-fourth of the bar, bounded by the x = 0.0 and x = 2.6585 planes, the y = 0.0 and 15.0 planes, and the z = 0.0 and z = 2.6585 planes, was positioned in the grid.

The target was initially bounded by the y=15.0~mm and 40.5 mm planes, the former being the front surface of the target. Since the bar's initial motion was in the positive y-direction, the boundary conditions at y-coordinate plane were specified to feed bar material into the grid as a simulation of a semi-infinite bar. The x-coordinate and z-coordinate planes were given reflective boundary conditions. The remainder of the planes, which bound the grid, were given transmittive boundary conditions in order to simulate an infinite target and to permit the flow of material out of the computational region.

The cells, occupying the initial volume of the penetrator, were given the following initial conditions:

- 1. Density = 8.9 Mg/m^3 .
- 2. Pressure = 0.0 Mbar.
- 3. X-component of velocity = 0.0 km/s.
- 4. Y-component of velocity = 7.5 km/s.
- 5. Z-component of velocity = 0.0 km/s.
- 6. Specific internal energy = 0.0 J/g.

Similar initial conditions were given to the cells occupying the initial volume of the target except that the density was that of the steel target material, $7.86~\text{Mg/m}^3$, and the y-component of the velocity was zero.

Tracer particles were positioned at 0.5-mm increments in the bar and target along the line of symmetry. Also, tracer particles were fed into the grid with the bar material being supplied into the computational grid. The motion of these tracer particles along the line of symmetry is shown in Figure 52. A transmitted and a reflected shock wave, located by the change in the direction of the tracer particle paths, emanate from the point of impact (y = 15.0 mm). Initially both of these waves have the speeds determined with the one-dimensional case. However, after about 0.30 μs , the rarefaction wave from the free surfaces of the bar reaches the line of symmetry of the bar and relieves the pressure in the shock wave moving into the bar. Having traveled no more than 2 mm from the point of impact, the shock wave turns and travels in the same direction as the bar.

Pressure profiles along the line of symmetry are shown in Figure 53 for the first 81 computational cycles (0.4 μs); however, only the odd numbered cycles are shown. Since the pressures are plotted in the centers of each cell, the initial rise in pressure occurs around y = 15.25 mm. In 13 cycles (0.10 μs) the pressure peaks after overshooting the theoretical shock pressure of 3.01 Mbar. Thereafter, the magnitude of the pressure profile decreases as the transmitted and reflected shock wave fronts form and move away from each other.

Pressure and particle velocity profiles along the line of symmetry are shown in Figures 54 - 57. The triangular symbol locates the position of the interface on the line of symmetry. The peak pressure of about 0.7 Mbar, shown at 2.0 μ s, persists until it is affected by the pressure release wave coming off the back surface of the target (y = 40.5 mm) at about 4.2 μ s.

Figure 58 shows pressure profiles at $0.5~\mu s$ intervals in the 15.25-mm y-plane, which is 0.25~mm from the front surface of the target, and the z-coordinate plane. The "radial" pressure in the bar, having a semi-thickness of 2.6585 mm, can be observed to be decreasing with time. Also, the propagation of the shock front in the x-direction is shown.

Tracer particles were also positioned along the free surfaces of the bar-target configuration in the z-coordinate plane. When the coordinates of these tracer particles are line-plotted as shown in Figures 59 - 61, the deformation of the bar and the target in the z-coordinate plane are depicted.

VIII. DISCUSSION AND CONCLUSIONS

Although one-dimensional shock-wave theory cannot be used to predict two and three-dimensional impact phenomena, it is useful for estimating one component of the overall grid size and the real time for running two- or three-dimensional problems on the computer.

The results of the one-dimensional finite-difference computations showed some of the characteristics of the DORF-9 code and the agreement of the results with one-dimensional shock-wave theory.

The effects of cylindrical and slab geometries and cylindrical and rectangular geometries are compared for several impact phenomena. A comparison of the motions of the shock waves, transmitted into the target at impact and reflected into the penetrator along the center line, is shown in Figure 63. The left graph shows that, as the thickness of the penetrator plate decreases, the motion of the transmitted shock waves approaches that of the rod. However, there is a limit to how thin a penetrator plate can be, since at least 3 or 4 computational cells should represent the semi-thickness of the plate. Furthermore, as the grid is made finer, the computational time increases.

The left graph in Figure 63 also shows the effect of penetrator plate thickness on the reflected shock wave: The thicker the plate is, the farther the reflected shock wave travels into the penetrator and the longer the time before the wave turns and moves in the direction of the penetrator. Note that the rod curve, after 2 μs , falls between the 3- and 4-mm plate curves.

The right side of Figure 63 shows the effects of rod and bar penetrators on the shock wave motion along the center lines. The transmitted wave motion is about the same for both penetrators; the reflected wave motion shows the effect of the rarefaction wave from the sides of the bar reaching the center line before the rarefaction wave from the surface of the rod.

The displacement of the center of the back of the target is shown in Figure 64. The bar and rod curves are in good agreement. As the penetrator plate thickness is decreased, the plate curves tend toward the rod curve; however, the agreement is poor. Furthermore, a comparison of the bulges on the back of the target at 5 μs (Figures 17 and 47) shows that the bulges are larger for the slab geometries than for the cylindrical geometry. Consequently, it would not be desirable, in spallation studies, to simulate three-dimensional impacts two-dimensionally.

A comparison of the penetration histories for cylindrical and slab geometries is shown in Figure 65. Initially, all the penetration motion is identical. Then the rod moves off at the greatest speed (slope). The curves for the 3- and 4-mm plates coincide and noticeably depart from the 6-mm plate after about 5 $\mu s.$ At any given time, the curves are no more than 0.7 mm apart.

⁹V. Kucher, "Preliminary Computer Computations for Slender Rod Impact Problems," Ballistic Research Laboratory Report No. 1957, Feb 1977. (AD #A036995)

Good agreement between the penetration for the rod and bar is depicted in Figure 66. Also illustrated is the fact that penetration rate cannot be determined by a one-dimensional finite-difference code.

The diameter or width, D, of the holes at the front surface of the target is shown in Figure 67 as they change with time. Decreasing the thickness of the penetrator plates decreases the rate of hole growth. The diameter of the hole initially made by the rod is the same as that of the 6-mm plate; eventually, the curve for the rod falls between the 3- and 4-mm plate curves. There is good agreement between the rod and bar curves.

Figure 68 is similar to Figure 67 except that D is measured in the middle of the target. The effect of the thickness of the plates is the same as that at the surface of the target. The curve for the rod falls between the 3- and 4-mm plate curves. At any time being considered, the average difference between the rod and bar curves is about 0.7 mm.

The propagation of pressure peaks normal to the center lines of the penetrators is shown in Figure 69. This motion occurs in the z=15.25-mm plane, just inside the front surface of the target. The penetrator plate curves differ mainly by constant time increments; this is also the case for the rod and bar curves.

Hole profiles for the cylindrical, slab, and retangular geometries at 5 μs are shown in Figure 70. The volume or size of the hole decreases as the penetrator plate thickness is decreased. The size of the hole made by the rod falls between the holes made by the 3- and 4-mm plates. The size of the hole made by the bar is smaller than that made by the rod. Note that at this time, the deepest penetration was made by the rod and the bar.

The comparisons that were made between the rod and the penetrator plates show how the results from slab geometry are to be interpreted if, for economical reasons or the unavailability of a three-dimensional code, the problem must be simulated by slab geometry. A penetrator plate, between 3- and 4-mm thick, could provide information on hole size, penetration, and reflected shock-wave motion, as a simulation of a 6-mm penetrator rod, that might be acceptable to the user.

The comparisons that were made between the rod and the bar indicate that, for the cross-sectional area being considered, the bar can be used to simulate a rod. It should be pointed out that, if the grid were made finer, the circular cross section of the rod could be approximated in rectangular coordinates.

The one-dimensional case required 50 computational cells; each of the two-dimensional cases, 5000 computational cells and a running time that was 20 times longer than the one-dimensional case. The three-dimensional case with 11,025 computational cells ran 2.5 times longer

than each of the two-dimensional cases. This running time would have been much longer if the grid size were of the same uniformity as for the two-dimensional cases. In this case, 250,000 computational cells would have been required.
